CARIÑO, JULIE R. APRIL 2009. <u>Effect of Green Manures on the Growth and</u> <u>Yield of High Yielding Varieties of Rice in Tuba, Benguet</u>. Benguet State University, La Trinidad Benguet.

Adviser: Leoncia L. Tandang, Ph.D.

ABSTRACT

This study was conducted to (1) evaluate the response of high yielding varieties (HYV's) of rice to green manuring; (2) determine the effect of green manure on the growth and yield of HYV's in Tuba, Benguet; (3) determine the interaction effect of variety and green manure on the growth and yield of rice; and (4) determine the profitability of growing HYV's of rice applied with green manures.

Significant differences among the green manures used were observed on the number of days to tillering and to booting, number of days from booting to heading, number of tillers at maximum tillering stage, number of productive tillers, length of panicle, height at maturity, grains per panicle and grain yield per plot and per hectare. Plants applied with madre de cacao had the highest grain yield.

Plants applied with sunflower were the earliest to boot and to ripen. Plants applied with ipi-ipil had the highest number of tillers while the unfertilized plants were the earliest to produce tillers and to boot but they were the latest to ripen. Madre de cacao was the best green manure in terms of all the parameters considered in this study particularly the grain yield per plot. Green manuring could play an important role to promote favorable soil properties and provide nutrition to the rice plant for a sustainable rice production.

The rice varieties tested significantly differed in terms of the parameters considered in this study. IR 64 had the tallest seedlings before transplanting, highest number of productive tillers and highest grain yield per plot and per hectare. IR 34 was the tallest at harvesting stage and had the longest panicle, but the latest to produce tillers, to boot and to ripen. PSB Rc 82 had the highest number of grains per panicle and the earliest to mature. Significant interaction effect of variety and green manures was observed on the number of days from transplanting to tillering, number of days from booting to heading and on the height of rice at maturity.

Based on the results of this study, farmers could grow IR 64 and IR 34 varieties of rice and use madre de cacao as green manure to produce good grain yield and to have the high return on cash expense.

INTRODUCTION

There is no possibility of expanding the areas devoted to planting rice. Presently, they are deliberately decreased because of the increasing demands for residential lots and the pressing need for areas devoted to industrial and business and establishment. To face this challenge of increasing production is to intensify production in existing fields and make production sustainable.

Rice (*Oryza sativa L.*) is well known cereal plant in warm and cool climates but usually rice plant grows faster in warm places. In the Philippines, wild and commercially grown varieties of rice are both preserved and are commonly grown because rice is the main staple crop of the Filipinos. According to UPCA (1983), rice production should be given priority so that the increasing population will have enough supply. Farmers should be encouraged to produce more to minimize the importation of rice. To increase rice production, adapted and high performing varieties and appropriate cultural management practices like fertilizer application must be considered. Since commercial fertilizers are expensive and excessive application of it makes the soil acidic, reduced farm nutrients and caused soil degradation and environment pollution. And to avoid this problem, organic farming might be a good solution to sustain productivity and replenish the soil depleted nutrients.

Rice production in the country had not yet come up to the level of sufficiency as shown by straggering quantities of rice importation yearly to fill up the difficiency. The use of organic fertilizer like compost may enlighten the farmers to improve soil properties which lead to increase the production of high yielding varieties of rice. Such farmers may utilize their ricelands to the fullest with high yields, and make the soil favorable and productive. The use of green manures is less expensive since it is abundantly available in the locality.

This study aimed to:

1. determine which high yielding varieties (HYV's) of rice is most responsive to green manuring;

2. determine the effect of green manure on the growth and yield of HYV's of rice in Tuba, Benguet;

3. determine the interaction effect of green manure and HYV's on the growth and yield of rice; and

4. to determine the profitability of growing HYV's of rice applied with green manure in Tuba, Benguet.

This study was conducted at farmer's field in Nangalisan Tuba, Benguet from December 2007 to April 2008.

REVIEW OF LITERATURE

About the Crop

Rice belongs to the Graminae family, subfamily Oryzoideae, tribe Oryzeae, genus Oryza. It is probably originated in India or Southeastern Asia. Oryza contains 22 species, both annual and perennial. Cultivated rice, both Asiatic and African, is an annual grass with culms terminated by loose panicle inflorescence having single, perfect flowered spikelets. Plants may reach 16 feet (deep water types in Southeast Asia) but most modern U.S. cultivars may reach 3 to 4 feet, culms are round and hallow except for nodes.Leaves are narrow, joined to sheaths and collars. Leaf auricles are well defined, sickle shaped and hairy in cultivated rice. Ligules may be acute to acuminate or may be biclefted (Smith, 1995).

Organic Rice Production

According to Sullivan (2003), leguminous green manure crops can supply 30% to 50% of the nitrogen needs of high yielding varieties of rice depending on the quantity, quality and type of green manure crop, the time and method of application, soil fertilizer, and cropping method. The clover provides enough nitrogen to produce high yield without additional nitrogen at one location. And it was found that organic rice price is two to three times higher than the conventionally grown rice but organic rice cost more to produce.

Importance of Organic Fertilizer

At present, rice growers are facing of many problems. One of which is the low soil fertility. Fertile lands that were successively cultivated for a long period have turned acidic due to inaccurate system of management.

Organic matter influences physical and chemical properties of the soil. It represents an accumulation of particularly synthesized plant and animal residues, which are continually broken down by the soil microorganism and consequently of a transitory soil constituent (Brandy, 1985).

Furthermore, soil high in organic matter tends to increase the population of microorganism and through this organism, it would eventually return to the soil in mineralized form.

Organic fertilizers generally provide the elements essential for the plant growth. It is at least 50% to 60% cheaper than inorganic fertilizer and is effective is increasing yield (Laurean, 1984). It can also maintain the soil good physical condition and increase the water holding capacity of the soil in a maximum utilization of the rain (Singh, 1983).

Effect of Organic Matter on Soil

Organic matter attract and hold cation nutrients and trace elements in an available state reducing leaching losses. Bind soil particles into aggregates, produced a granular structure which permits the accessibility of air to roots, the capillary movement of water and the penetration roots through the soil. Organic matter are transformed into vitamins, hormones and other substances which stimulate growth in plants and microorganism (Parnes, 1986).

Kinoshita (1970), revealed that organic matter turn heavy soil lighter, more crumbly, friable and hold light soil particles to act as an anchor against erosion and to increase the water holding capacity of the soil. They provide some of the large quantities of nitrogen needed by the plants and release nutrients present in the soil by turning them into soluble compound that can be absorbed by the roots of the plants. Finally, they carry considerable quantity of elements often insufficient in the soil and provide readily available microelements, both activities promote plant growth.

Effect of Organic Fertilizer to Plant Growth

Soil vary in their capacity to supply the mineral nutrients for the plants factors. Responsible for the variation are soil origin, stage of soil development, organic matter content and soil management practices with passage of time individual elements in the soil minerals are slowly released ions capable of being taken up by plants. The rate of this release dependent on factors such as the kind of soil minerals climate, vegetation growing on the soil (Pandy,1987).

Some local experiments have been conducted on the use of organic fertilizer. In 1976, Mejia work on sweet pepper and she found out that different organic fertilizer had variable effect on the growth of the plants. The applied 4 tons of chicken dung per hectare registered the highest weight of roots and vegetative growth.

Bal- iwang (1994), found out the different fertilizers had variable effect on the rice growth. The rice plant applied with two tons of chicken dung per hectare registered the highest plant at maturity and highest number of productive tillers.

The addition of manure increased the rate of growth of rice plants. Manures materially hastened the emergence of the panicles of the rice plants during dry season,

but did not increase the tillers of the plants and yield during wet season (Ballesteros, 1949).

Effect of Sunflower

Pandosen (1986), stated that in the absence of manure, wild sunflower that is abundant in highland can be perfect substitute for organic nitrogen source. Sunflower is quite easy to compost and it hastens decomposition. Furthermore, she stated that wild sunflower has been known to be good supplementary source of organic nitrogen. Fresh sunflower contains 3.76 % N and wild sunflower based compost has 3.22% N. Besides being free, wild sunflower is readily available in the Cordillera region. The use of wild sunflower as a source of organic N may provide important findings related to minimizing the use of inorganic N and could be good basis for recommendation.

Effect of Ipil - Ipil

Ipil –ipil is an excellent source of organic fertilizer and soil improver, and it is being used as a fertilizer and erosion controller in corn, tobacco and onions according to Benge (1977). Application of ipil – ipil leaves as organic fertilizer is as effective as the commercial inorganic fertilizer (ammonium sulfate) in providing ammonium nutrition of rice both under flooded and non flooded condition.

Effect of Madre de Cacao

Madre de cacao also locally known as kakawete is a nitrogen fixing tree. It is used as ripening agent of harvested banana and can be utilized as fertilizer to lessen the farm inputs. Application of organic materials just like madre de cacao is a good agricultural practice to maintain soil nutrient level and ameliorate the properties of soil to

sustain crop production. Effect on the crops performance and yield as well as its beneficial effect on the soil physical and chemical properties, further study is strongly recommended. Similarly, the economic benefits of applying organic materials as soil amendment and its potential as an alternative to inorganic fertilizers should also be evaluated (Archives 2004).

Effect of Green Manures on Soil Organic Matter

According to MacRae (2009), green manures affect the microbial activity of the soil and it is generally accepted that low- nitrogen green manures (1.5% N or less) can be effective in improving soil organic matter levels. Furthermore, stated that it is also improved soil physical conditions create the potential for increased crop growth.

Importance of High Yielding Varieties (HYV's)

The use of high yielding varieties (HYV's) can lessen the production cost and ease the burdens of the farmers according to Sallatic (1999). Due to their earliness in maturity than the traditional varieties, two croppings in a year could result in greater production and profit. Vergara (1992), stated that modern varieties of the high yielding varieties of rice gave greater potential than traditional varieties even under the best condition. Traditional varieties do not yield more than modern varieties.

Pests and Diseases

Rice bug locally known as "atangya" in Tagalog and "dangaw" in Ilocano, sucks the content of the rice grain during milk stage resulting to empty grains. On the other hand, rice blast is one of the most destructive fungal disease of rice. It inflicts as much as 50% loss areas where severe outbreaks occur. However, rice blast is controlled by planting

resistant varieties, integrated with some cultural management practices which include raising seedling in wetland condition (UPLB, 1983).

Disease and insect problems are common in rainfed lowland rice environment which are more serious during rice second crop. However, for the successful production of rice crops, rice cultivars planted should be resistant to insects, pests and disease like stemborers and rice bugs which are the common insect problem as well as bacterial blight and brown spot (Ingram, 1995).

MATERIALS AND METHODS

An area of 216 sq m. was thoroughly prepared for wet seedbeds. The area was divided into three blocks representing three replications. Each replication was subdivided into 12 plots measuring 1m x 5m each. Earthened bunds measuring 20 cm wide and 30 cm high were constructed in between treatments to avoid fertilizer mixing during irrigation.

The different green manures were mixed thoroughly with the soil during last harrowing which was one week before transplanting. One rice seedling per hill was transplanted in a straight row with a distance of 20 cm between hills and 20 cm between rows. The experiment was laid out following 3 x 4 factor–factorial arrangement in Randomized Complete Block Design (RCBD) with three replications. The high yielding varieties (HYV's) were considered as Factor A and the different green manures were considered as Factor B.

| Factor A: High Yielding Variety (V) | Factor B: Green Manure (GM) |
|-------------------------------------|---------------------------------------------|
| V ₁ -IR 64 | GM ₀ – no fertilizer/control |
| V ₂ - IR 34 | GM_1 – Sunflower (5kg/plot) |
| V ₃ - PSB Rc 82 | GM ₂ – Madre de cacao (5kg/plot) |
| | GM ₃ – Ipil – ipil (5kg/plot) |

Hand weeding was done 20 days after transplanting. From then on the plots were kept weed free. Insect pests and diseases were controlled and monitored to reduce economic losses. Other recommended cultural management practices were followed to ensure better yield.

Soil samples were gathered from the experimental area before and after the study to determine the pH, organic matter (OM), nitrogen, potassium, and phosphorus content at Baguio Soils Laboratory Pacdal, Baguio City for initial analysis and at the Bureau of Soils San Fernando City, La Union for final analysis.

Data Gathered:

1. <u>Height of seedling before transplanting (cm)</u>. The height of rice seedlings before transplanting was measured from the base of the plant to the longest leaf before transplanting using 10 samples per plot.

Number of days from transplanting to tillering. This was recorded when at least
 50% of the total plants per plot started producing tillers.

3. <u>Number of tillers at maximum tillering stage</u>. This was counted and recorded when 50 % of the total plants in each plot produced flag leaf.

4. <u>Number of productive tillers</u>. The number of productive tillers were counted using 10 random sample hills per plot.

5. <u>Number of days from transplanting to booting</u>. This was taken when at least 50% of the total plants in a plot booted.

6. <u>Numbers of days from booting to heading</u>. This was taken when at least 50% of the total plants in a plot produced heads.

7<u>. Length of panicle (cm).</u> This was taken by measuring the panicle from its base up to the tip of the last grain excluding the awn for ten sample plants per treatment.

8. <u>Plant height at maturity (cm)</u>. The height of the plants was measured from the base of the plant at ground level to the tip of the longest panicle at harvest using ten random sample hills per plot.

9. <u>Number of grains per panicle</u>. This was taken using ten random panicle samples per plot.

10. <u>Grain yield per plot $(kg/5m^2)$ </u>. This was taken by removing the grains after drying the grains and separating the filled grains from the unfilled grains. Only the weight of filled grains per plot was recorded.

11. <u>Computed grain yield per hectare (t/ha)</u>. This was taken by converting the weight of filled grains per plot into yield per hectare using the following formula:

Yield/ hectare (t/ha) =
$$\frac{\text{Yield (kg)}}{5m^2}$$
 x 2

Where 2 was the factor used to convert yield per plot in $kg/5m^2$ to computed yield per hectare in t/ha using one hectare effective area.

12. <u>Resistance to lodging</u>. This was recorded at maturity using the following scale used by Phil Rice (1996):

| <u>Scale</u> | Description | Remarks |
|--------------|--------------|------------------------|
| 1 | No lodging | Resistant |
| 2 | 25% lodging | Moderately resistant |
| 3 | 50% lodging | Moderately susceptible |
| 4 | 75% lodging | Susceptible |
| 5 | 100% lodging | Very susceptible |

13.<u>Reaction to stemborer</u>. Evaluation of stem borer infestation expressed in percent whiteheads was done at heading time using the following standard scale (Phil Rice, 1996):

| Rating index | % Whiteheads | Remarks |
|--------------|--------------|------------------------|
| 1 | 1-5 | Tolerant |
| 2 | 6-10 | Moderately tolerant |
| 5 | 11-15 | Intermediate |
| 7 | 16-25 | Moderately susceptible |
| 9 | 26-above | Susceptible |

14. <u>Reaction to blast (neck rot)</u>. Evaluation on the severity of rice blast or neck rot was taken from the plants at the center rows, using the following formula for infection and rating scale used by Phil Rice (1996):

| Percent Infection = $\frac{\text{No. of panicles infected}}{\text{Total No. of panicle considered}} \times 100$ | | | |
|-----------------------------------------------------------------------------------------------------------------|---------------------------|--------------|--|
| Index | Percent Blast infectation | Remarks | |
| 1 | 0-5 | Resistant | |
| 2 | 6-25 | Intermediate | |
| 3 | 26-above | Susceptible | |

16. <u>Return on cash expenses (ROCE)</u>. The total production costs per plot were recorded and net profit was computed. The return on cash expenses was computed using the following formula:

$$ROCE = \underbrace{Net \text{ profit}}_{Total \text{ cost production}} x 100$$

Data Analysis

All the quantitative data gathered in this study were statistically analyzed using the 3 x 4 factor- factorial arrangement in Randomized Complete Block Design (RCBD) with three replications. The significance of differences among treatment means was determined using the F- test and Duncan's Multiple Range Test (DMRT) at 5% level 0f significance.

RESULTS AND DISCUSSION

Soil Chemical Properties

Table 1 shows the result of the soil analysis before planting and after harvesting. Before planting the soil pH was below 6.0 and there was an increase in pH after harvesting. The organic matter of the experimental plots also increased. Likewise, the N, P and K contents of the soil also increased. This finding indicated that the application of green manure in the rice field increased the chemical properties of the soil.

Plant Height at Seedling Stage and at Maturity

<u>Variety.</u> The seedlings of IR 64 and IR 34 were taller than the seedlings of PSB Rc 82 (Table 2). At maturity, the height of plants among varieties tested was comparable.

<u>Green manure.</u> The different green manures used in this study did not significantly affect the plant height at seedling stage. The green manures incorporated in plots increased the plant height of rice at maturity (Table 2). Plants applied with madre de

| TREATMENT | рН | OM | N | Р | К |

| Ipil- ipil | 6.2 | 3.5 | 0.66 | 35 | 43 |
| | | | | | |

Table 1. Soil chemical properties

cacao were the tallest. This was followed by those plants applied with ipil – ipil and sunflower. Finally, the unfertilized plants were the shortest. This results shows that rice plants responded well when applied with green manure. This probably was due to nitrogen content of the green manures used that enhanced growth of HYV's.

Interaction effect. Varieties and green manures did not significantly interact on the height of seedling before transplanting. The varieties and green manures had significantly interaction effect on plant height of rice at maturity (Table 2). Without green

*Means with the same letters are not significantly different at 5 % level using DMRT.

manure IR 34 had the tallest plant but with sunflower as green manure all the three HYV's had comparable plant height. With madre de cacao and ipil–ipil as green manure, IR 34 produced the tallest plants among the three HYV's evaluated (Figure 1).

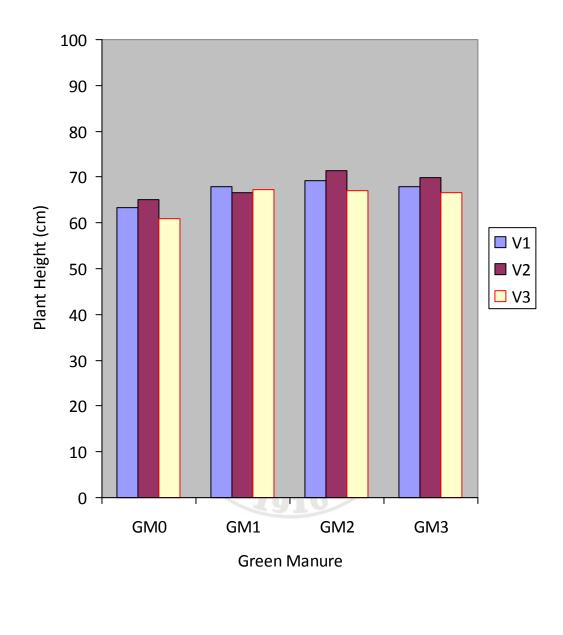

<u>Maturity</u>

<u>Variety</u>. Table 3 shows that PSB Rc 82 was the earliest to produce tiller, boot and ripen from transplanting among the three rice varieties used in this study. PSB Rc 82 took about two weeks from booting to heading and it reached heading 2 days earlier than the other two varieties of rice studied.

Green manure. Significant differences were noted among the plants applied with different green manures used in terms of the number of days from transplanting to tillering, booting and ripening. The plants applied with green manures produced tillers two days after tillering of unfertilized plants. However, they booted and ripened one day earlier than the unfertilized plants except for those applied with ipil- ipil which ripened at similar days with plants grown in plots without green manure. Application of fertilizers hasten the number of days from booting to heading of rice by one day earlier than the unfertilized one (Table 3). According to Vergara (1992), fertilizers hastened earlier flowering and maturity of rice plants because of their nutrient contents which gave faster effect on the growth and development of rice plants.

Interaction effect. Highly significant interaction effect of varieties and green manure applied was observed on the number of days from booting to heading of rice (Fig. 3). The three HYV's had almost similar response to all green manures applied in terms of days from booting to heading. Only PSB Rc 82 was the earliest to heading from booting

| Legend: Variety (V) | Green Manures (GM) |

while IR 64 and IR 34 formed head from booting at the same period regardless of green manure applied.

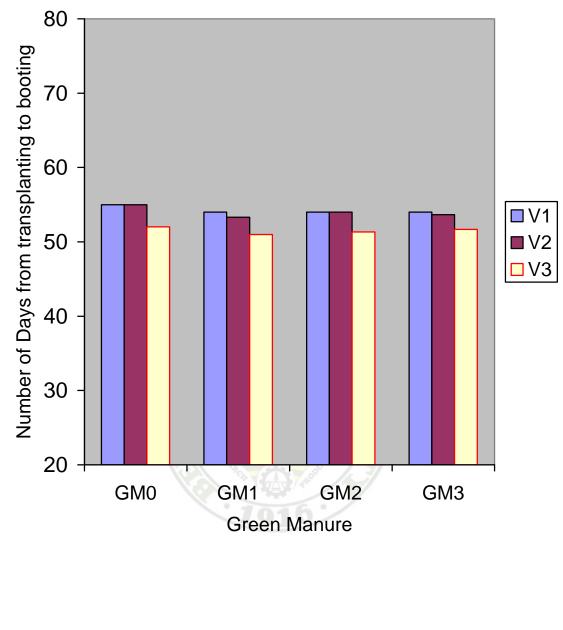

Number of Tillers and Productive Tillers Per Hill

<u>Variety.</u> No significant differences on the number of tillers at maximum tillering stage of rice was observed among the three rice varieties tested (Table 4). IR 64 produced more than 9 tillers per hill while both IR 34 and PSB Rc 82 produced ten tillers per hill. PSB Rc 82 had the lowest number of productive tillers per plant among the HYV's

studied. IR 64 had the highest number of productive tillers which was followed by IR 34 (Table 4).

<u>Green manure</u>. Green manure application significantly increased the number of tiller per plant by one tiller than those of the unfertilized plants (Table 4). The unfertilized plants produced the highest number of productive tillers followed by the plants applied with ipil- ipil and with madre de cacao. The lowest number of productive tillers was recorded in plants applied with sunflower.

 Table 4. Number of tillers per hill at maximum tillering stage and productive tillers per hill of the rice varieties applied with different green manures

*Means with the same letters are not significantly different at 5 % level using DMRT.

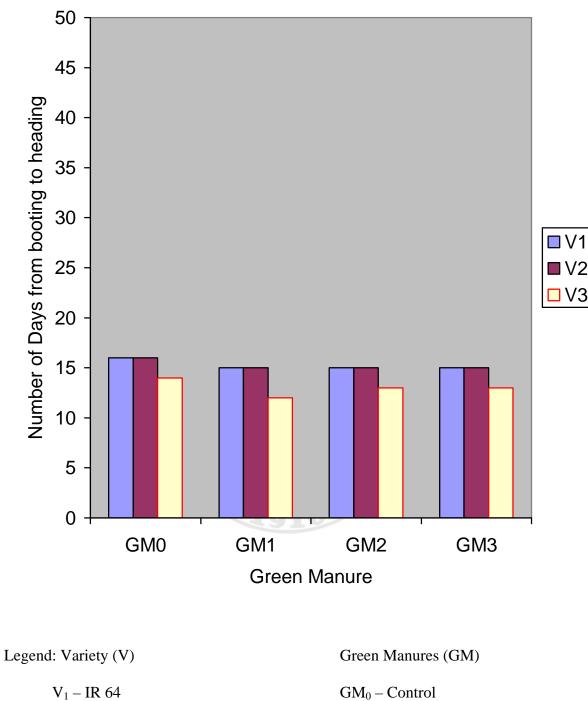

Interaction effect. There was no significant interaction effect of rice varieties and green manures used on the number of tillers at maximum tillering stage of rice. According to Yoshida (1981) the tillering performance of rice is related to the nutrient status of the plant that is the more nutrients present, the more tillers to produced. Varieties and green manures had no significant interaction effect on the number of productive tillers (Table 4). In order to produce more tillers according to PhilRice (1991) rice plants need adequate NPK content of the soil. Probably the amount of nutrients supplied by green manures mixed with the soil in plots, were not yet available for rice utilization to produce numerous and productive tillers.

Length of Panicle

<u>Variety.</u> IR 64 and IR 34 recorded longer panicle than PSB Rc 82 (Table 7). Rice plants applied with madre de cacao had the longest panicle of 69.27 cm. It did not significantly differ from the panicle length measured in plants applied with ipil – ipil but significantly different from the length recorded from the plants applied fertilized with sunflower. This could be attributed to better growth and development of rice plants applied with green manures.

<u>Green manure.</u> The plants grown in plots without green manure had the shortest panicle. This goes with the findings of Sung-ag in 1997 that application of organic fertilizer produce longer panicles and due to availability of sufficient NPK from the fertilizer used.

Figure 3. Interaction effect of rice varieties and green manures on number of days from booting to heading

<u>Interaction effect</u>. Different green manures and rice varieties tested in this study did not significantly interact with each other on the length of panicle of rice.

Number of Grains per Panicle

Variety. PSB Rc 82 had the higher number of grains per panicle than both IR 34 and IR 64 (Table 5).

<u>Green manure</u>. Green manure application significantly enhanced the number of grains per panicle. Plants applied with madre de cacao and ipil – ipil recorded the highest number of grains per panicle and the lowest was recorded in plants grown without green

manure. This finding indicates that green manure increases grain number per panicle. This confirmed the findings of Donahue (1978), who further stated that fertilizers specially their NPK contents aid in seed formation.

<u>Interaction effect</u>. No significant interaction effect between the green manures used and the varieties of rice tested was noted on the number of grains per panicle of rice.

Yield per Plot and per Hectare

<u>Variety</u>. IR 64 and IR 34 gave comparatively higher yield per plot and per hectare than PSB Rc 82 (Table 6 and Fig. 4). PSB Rc 82 had lower yield because it was affected

by rice blast and had the lowest number of productive tillers.

<u>Green manure</u>. Green manure application increased the grain yield per plot and per hectare of rice. The plants without green manure produced the lowest yield per plots and per hectare. The plants applied with madre de cacao recorded the highest yield per plot and per hectare. Plants applied with sunflower and ipil-ipil produced higher yield than the plants grown in plots without green manure.

<u>Interaction effect</u>. The different kinds of green manures and varieties of rice tested did not have significantly interaction effect on the grain yield of rice (Table 6).

Resistance to Lodging, Stemborer and Rice Blast

All varieties used were resistant to lodging. The plants grown without green manure were noted to have moderately resistance to lodging while plants with different green manures were all rated resistant to lodging.

Similarly, all the HYV's used were resistance to whiteheads caused by stemborer and rice blasts. Green manures did not significantly affect resistance of rice to stemborer and rice blast. Furthermore, there was no significant interaction effects of HYV's and green manures on lodging, stemborer and rice blast of rice.

Cost and Return analysis

IR 64 gave the highest gross income of 60.50 with a total expenses of 35.00 and a net income of P25.50. the PSB Rc 82 registered the lowest with P 52.50 gross income and a net income of P17. 50. A positive return on cash expenses (ROCE) was observed in All the varieties tested. IR 64 obtained the highest ROCE of 72.86% and PSB Rc 82 had the lowest ROCE of 50.00% (Table 7).

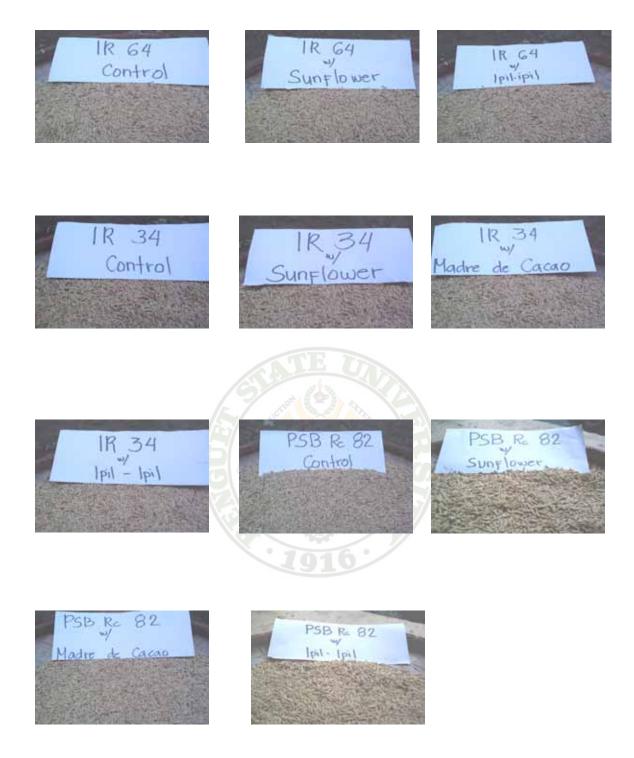

Figure 4. Grains of the rice varieties applied with different green manures

A positive ROCE was noted in rice grown in plots without green manure and in plots with madre de cacao. Negative net income and ROCE were noted in plants applied with sunflower and ipil – ipil as green manures. This is due to lower yield and high of production cost increased like in the plots without green manure which had the lowest yield and low cost of production so it gave highest ROCE.

SUMMARY, CONCLUSIONS AND RECOMMENDATIONS

<u>Summary</u>

The study was conducted to evaluate the response of high yielding varieties (HYV's) of rice to green manuring; to determine the effect of green manure on the growth and yield of HYV's of rice to determine the interaction effect of variety and green manure on the growth and yield of rice; and to determine the profitability of growing HYV's of rice applied with green manures in Tuba, Benguet.

Based on the result of the study, the rice varieties tested were significantly different in all the parameters studied. IR 64 had the tallest seedling before transplanting, highest number of productive tillers and highest grain yield per plot and hectare. IR 34 was the tallest at harvest and had longest panicle, and latest to produce tillers, to boot and to ripen. PSB Rc 82 had the highest number of grains per panicle and was the earliest to mature. IR 64 and IR 34 could be grown because of their good growth and yield in Tuba, Benguet.

Significant differences among the green manures used were observed on the days to tillering and to booting, days from booting to heading, and days from heading to ripening, number of tillers at maximum tillering stage, number of productive tillers, length of panicle, height at maturity, grains per panicle and grain yield per plot and per hectare. Plants applied with madre de cacao had the tallest seedling before transplanting, tallest plant at maturity, longest panicle and highest number of grains per panicle and grain yield. Plants applied with sunflower were the earliest to boot and to ripen. Plants applied with ipil-ipil had the highest number of tillers. The unfertilized plants were the earliest to produce tillers, to boot but latest to ripen, and gave the lowest grains per panicle and grain yield. Among the green manures applied, madre de cacao was the best because it gave the highest yield. Green manuring could play an important role to promote favorable soil properties and provides nutrition to the rice plant for a sustainable rice production.

Significant interaction effect of variety and green manure was observed on the number of days from transplanting to booting, number of days from booting to heading and on the height at maturity.

Conclusions

Based on the results of the study, IR 64 and IR 34 are the most responsive HYV's to green manuring because they exhibited good growth and high grain yield.

The different fertilizers applied significantly affect the number of days from transplanting to tillering, booting and ripening, number of days from booting to heading, plant height at maturity, number of tillers at maximum tillering stage, number of productive tillers, length of panicle, number grains per panicle and yield per plot and computed yield per hectare.

High yielding varieties of rice and green manures had significant interaction effect on maturity and plant height of rice at harvest.

Recommendations

Based on the results of the study, IR 64 and IR 34 could be grown in Tuba, Benguet due to their relatively higher tillers and number of grains per panicle and grain yield. They were also found to be resistant to stemborer and rice blast. Green manures
